Bioinformatics 3 V 5 – Robustness and Modularity

Mon, Nov 9, 2015

Network Robustness

Network = set of connections

Failure events: • loss of edges

- loss of nodes (together with their edges)
- \rightarrow loss of connectivity
 - paths become longer (detours required)
 - connected components break apart
 - \rightarrow network characteristics change

→ Robustness = how much does the network (not) change when edges/nodes are removed

Error and attack tolerance of complex networks

Réka Albert, Hawoong Jeong & Albert-László Barabási

Department of Physics, 225 Nieuwland Science Hall, University of Notre Dame, Notre Dame, Indiana 46556, USA

Many complex systems display a surprising degree of tolerance against errors. For example, relatively simple organisms grow, persist and reproduce despite drastic pharmaceutical or environmental interventions, an error tolerance attributed to the robustness of the underlying metabolic network¹. Complex communication networks² display a surprising degree of robustness: although key components regularly malfunction, local failures rarely lead to the loss of the global information-carrying ability of the network. The stability of these and other complex systems is often attributed to the redundant wiring of the functional web defined by the systems' components. Here we demonstrate that error tolerance is not shared by all redundant systems: it is displayed only by a class of inhomogeneously wired networks,

Network Fragmentation

<s>: average size of the isolated clusters (except the largest one)

S: relative size of the largest cluster S; this is defined as the fraction of nodes contained in the largest cluster (that is, S = 1 for f = 0)

Random network:

- no difference between attack and failure (homogeneity)
- fragmentation threshold at $f_c \gtrsim 0.28$ (S ≈ 0)

Scale-free network: • delayed fragmentation and isolated nodes for failure

• critical breakdown under attack at $f_c \approx 0.18$

Modularity: an example of graph partitioning

The simplest graph partitioning problem is the division of a network into just 2 parts. This is called **graph bisection**.

If we can divide a network into 2 parts, we can also divide it further by dividing one or both of these parts ...

graph bisection problem: divide the vertices of a network into 2 non-overlapping groups of given sizes such that the **number of edges** running **between** vertices in **different groups is minimized**.

The number of edges between groups is called the cut size.

In principle, one could simply look through all possible divisions of the network into 2 parts and choose the one with smallest cut size.

Algorithms for graph partitioning

But this exhaustive search is prohibitively expensive!

Given a network of *n* vertices. There are $\frac{n!}{n_1!n_2!}$ different ways of dividing it into 2 groups of n_1 and n_2 vertices.

The amount of time to look through all these divisions will go up roughly exponentially with the size of the system.

Only values of up to n = 30 are feasible with current computers.

In computer science, either an algorithm can be clever and run quickly, but will fail to find the optimal answer in some (and perhaps most) cases, or it will always find the optimal answer, but takes an impractical length of time to do it.

The Kernighan-Lin algorithm

This algorithm proposed by Brian Kernighan and Shen Lin in 1970 is one of the simplest and best known heuristic algorithms for the graph bisection problem. (Kernighan is also one of the developers of the C language).

(a) The algorithm starts with any division of the vertices of a network into two groups (shaded) and then searches for pairs of vertices, such as the pair highlighted here, whose interchange would reduce the cut size between the groups.

(b) The same network after interchange of the 2 vertices.

The Kernighan-Lin algorithm

(1) Divide the vertices of a given network into 2 groups (e.g. randomly)

- (2) For each pair (*i*,*j*) of vertices, where *i* belongs to the first group and *j* to the second group, calculate how much the cut size between the groups would change if *i* and *j* were interchanged between the groups.
- (3) Find the pair that reduces the cut size by the largest amount.
 - If no pair reduces it, find the pair that increases it by the smallest amount.
- Repeat this process, but with the important restriction that each vertex in the network can only be moved once.

Stop when there is no pair of vertices left that can be swapped.

The Kernighan-Lin algorithm (II)

- (3) Go back through every state that the network passed through during the swapping procedure and choose among them the state in which the cut size takes its smallest value.
- (4) Perform this entire process repeatedly, starting each time with the best division of the network found in the last round.
- (5) Stop when no improvement on the cut size occurs.

Note that if the initial assignment of vertices to group is done randomly, the Kernighan-Lin algorithm may give (slightly) different answers when it is run twice on the same network.

The Kernighan-Lin algorithm (II)

(a) A mesh network of 547 vertices of the kind commonly used in finite element analysis.

(b) The best division found by the Kernighan-Lin algorithm when the task is to split the network into 2 groups of almost equal size.

This division involves cutting 40 edges in this mesh network and gives parts of 273 and 274 vertices.

(c) The best division found by spectral partitioning (alternative method).

Runtime of the Kernighan-Lin algorithm

The number of swaps performed during one round of the algorithm is equal to the smaller of the sizes of the two groups $\in [0, n/2]$.

 \rightarrow in the worst case, there are O(n) swaps.

For each swap, we have to examine all pairs of vertices in different groups to determine how the cut size would be affected if the pair was swapped.

In the worst case, there are $n/2 \times n/2 = n^2/4$ such pairs, which is $O(n^2)$.

Runtime of the Kernighan-Lin algorithm (ii)

When a vertex *i* moves from one group to the other group, any edges connecting it to vertices in its current group become edges between groups after the swap.

Let us suppose that are k_i^{same} such edges.

Similarly, any edges that *i* has to vertices in the other group, (say k_i^{other} ones) become within-group edges after the swap.

There is one exception. If *i* is being swapped with vertex *j* and they are connected by an edge, then the edge is still between the groups after the swap

 \rightarrow the change in the cut size due to the movement of *i* is $k_i^{other} - k_i^{same} - A_{ij}$

A similar expression applies for vertex *j*.

 \rightarrow the total change in cut size due to the swap is $k_i^{other} - k_i^{same} + k_i^{other} - k_i^{same} - 2A_{ii}$

Runtime of the Kernighan-Lin algorithm (iii)

For a network stored in adjacency list form, the evaluation of this expression involves running through all the neighbors of *i* and *j* in turn, and hence takes time on the order of the average degree in the network, or O(m/n) with *m* edges in the network.

 \rightarrow the total running time is $O(n \times n^2 \times m/n) = O(mn^2)$

On a sparse network with $m \propto n$, this is $O(n^3)$

On a dense network (with
$$m \rightarrow \frac{n(n-1)}{2}$$
), this is $O(n^4)$

This time still needs to be multiplied by the number of rounds the algorithm is run before the cut size stops decreasing.

For networks up to a few 1000 of vertices, this number may be between 5 and 10.

Mesoscale properties of networks - identify cliques and highly connected clusters

Most relevant processes in biological networks correspond to the mesoscale (5-25 genes or proteins) not to the entire network.

However, it is computationally enormously expensive to study mesoscale properties of biological networks.

e.g. a network of 1000 nodes contains 1×10^{23} possible 10-node sets.

Spirin & Mirny analyzed combined network of protein interactions in *S. cereviseae* with data from CELLZOME, MIPS, BIND: 6500 interactions.

Identify connected subgraphs

The network of protein interactions is typically presented as an undirected graph with proteins as nodes and protein interactions as undirected edges.

First aim: identify **fully connected subgraphs** (cliques) A clique is a set of nodes that are all neighbors of each other.

The "maximum clique problem" – finding the largest clique in a given graph is known be NP-hard.

In this example, the whole graph is a clique and consequently any subset of it is also a clique, for example {*a*,*c*,*d*,*e*} or {*b*,*e*}.

A **maximal clique** is a clique that is not contained in any larger clique. Here only *{a,b,c,d,e}* is a maximal clique.

In general, protein complexes need not to be fully connected.

Spirin, Mirny, PNAS 100, 12123 (2003)

Identify all fully connected subgraphs (cliques)

Although the general problem - finding all cliques of a graph - is very hard, this can be done relatively quickly for the given network because the protein interaction graph is quite sparse (the number of interactions (edges) is similar to the number of proteins (nodes).

To find cliques of size *n* one needs to enumerate only the cliques of size *n*-1.

The search for cliques starts with n = 4, pick all (known) pairs of edges (6500 × 6500 protein interactions) successively. For every pair *A*-*B* and *C*-*D* check whether there are edges between *A* and *C*, *A* and *D*, *B* and *C*, and *B* and *D*. If these edges are present, *ABCD* is a clique.

For every clique identified, *ABCD*, pick all known proteins successively. For every picked protein *E*, if all of the interactions *E-A*, *E-B*, *E-C*, and *E-D* exist, then *ABCDE* is a clique with size 5.

Continue for *n* = 6, 7, ... The largest clique found in the protein-interaction network has size 14. Spirin, Mirny, PNAS 100, 12123 (2003)

Bioinformatics 3 – WS 15/16

Identify all fully connected subgraphs (cliques)

These results include, however, many redundant cliques. For example, the clique with size 14 contains 14 cliques with size 13.

To find all nonredundant subgraphs, mark all proteins comprising the clique of size 14, and out of all subgraphs of size 13 pick those that have at least one protein other than marked.

After all redundant cliques of size 13 are removed, proceed to remove redundant twelves etc.

In total, only 41 nonredundant cliques with sizes 4 - 14 were found by Spirin & Mirny.

Spirin, Mirny, PNAS 100, 12123 (2003)

Statistical significance of cliques

Number of complete cliques as a function of clique size enumerated in the network of protein interactions (red) and in randomly rewired graphs (blue, averaged over >1,000 graphs where the number of interactions for each protein is preserved).

Inset shows the same plot on a log-normal scale. Note the dramatic enrichment in the number of cliques in the protein-interaction graph compared with the random graphs. Most of these cliques are parts of bigger complexes and modules.

Spirin, Mirny, PNAS 100, 12123 (2003)

Reducing Network Complexity?

TEG1

Is there a **representation** that highlights the **structure** of these networks???

Abstract

We introduce an algorithmic method, termed modular decomposition, that defines the organization of protein-interaction networks as a hierarchy of nested modules. Modular decomposition derives the logical rules of how to combine proteins into the actual functional complexes by identifying groups of proteins acting as a single unit (sub-complexes) and those that can be alternatively exchanged in a set of similar complexes. The method is applied to experimental data on the pro-inflammatory tumor necrosis factor- α (TNF- α)/NF κ B transcription factor pathway.

Genome Biology **5** (2004) R57

Shared Components

Shared components = proteins or groups of proteins occurring in different complexes are fairly common. A shared component may be a small part of many complexes, acting as a **unit** that is constantly **reused** for its function.

Also, it may be the **main part** of the complex e.g. in a family of variant complexes that differ from each other by distinct proteins that provide functional specificity.

<u>Aim</u>: **identify** and properly **represent** the modularity of protein-protein interaction networks by identifying the **shared components** and the way they are arranged to generate **complexes**.

Gagneur et al. Genome Biology 5, R57 (2004)

Georg Casari, Cellzome (Heidelberg)

Modular Decomposition of a Graph

Module := set of nodes that have the same neighbors outside of the module

trivial modules: {a}, {b}, ..., {g} {a, b, ..., g} non-trivial modules: {a, b}, {a, c}, {b, c} {a, b, c} {e, f}

Quotient: representative node for a module

Iterated quotients \rightarrow labeled tree representing the original network \rightarrow "modular decomposition"

Quotients

Series: all included nodes are direct neighbors (= clique)

Parallel: all included nodes are non-neighbors

Prime: "anything else" (best labeled with the actual structure)

A Simple Recursive Example

Gagneur et al, *Genome Biology* **5** (2004) R57

Using data from protein complex purifications e.g. by TAP

Different types of data:

• Y2H: detects direct physical interactions between proteins

• PCP by tandem affinity purification with mass-spectrometric identification of the protein components identifies multi-protein complexes

 \rightarrow Molecular decomposition will have a **different meaning** due to different **semantics** of such graphs.

Here, we focus analysis on **PCP content** from TAP-MS data.

PCP experiment: select bait protein where TAP-label is attached \rightarrow Co-purify protein with those proteins that co-occur in at least one complex with the bait protein.

Gagneur et al. Genome Biology 5, R57 (2004)

Data from Protein Complex Purification

Graphs and module labels from systematic PCP experiments:

(a) Two neighbors in the network are proteins occurring in a same complex.

(b) Several potential sets of complexes can be the origin of the same observed network. Restricting interpretation to the simplest model (top right), the **series** module reads as a logical AND between its members.

(c) A module labeled **'parallel'** corresponds to proteins or modules working as strict alternatives with respect to their common neighbors.

(d) The **prime** case is a structure where none of the two previous cases occurs.

Gagneur et al. Genome Biology 5, R57 (2004)

Real World Examples

Two examples of modular decompositions of protein-protein interaction networks.

In each case from top to bottom: schemata of the complexes, the corresponding protein-protein interaction network as determined from PCP experiments, and its modular decomposition (MOD).

(a) Protein phosphatase 2A.

Parallel modules group proteins that do not interact but are functionally equivalent.

Here these are the catalytic proteins Pph21 and Pph22 (module 2) and the regulatory proteins Cdc55 and Rts1 (module 3), connected by the Tpd3 "backbone".

other decompositions also possible

Bioinformatics 3 – WS 15/16

Summary

Modular decomposition of graphs is a well-defined concept.

 One can proof thoroughly for which graphs a modular decomposition exists.

• Efficient O(m + n) algorithms exist to compute the decomposition.

However, experiments have shown that **biological** complexes are **not strictly disjoint**. They often share components

 \rightarrow separate complexes do not always fulfill the strict requirements of modular graph decomposition.

Also, there exists a "danger" of false-positive or false-negative interactions.

→ other methods, e.g., for detecting communities (Girven & Newman) or densely connected clusters are more suitable for identification of complexes because they are more sensitive.

Power Graph Analysis

Power Graph Analysis Algorithm

Two **conditions**:

power node hierarchy condition:

two power nodes are either disjoint, or one is included in the other one

 power edge disjointness condition: each edge of the original graph is represented by one and only one power edge

Algorithm:

1) identify potential power nodes with hierarchical clustering based on neighborhood similarity

2) greedy power edge search

Royer et al, PLoS Comp Biol 4 (2008) e1000108

Complex = Star or Clique?

Figure 1. The Three Basic Motifs: Star, Biclique, and Clique. Stars often occur because of hub proteins or when affinity purification complexes are interpreted using the spoke model. Bicliques often arise because of domain-domain or domain-motif interactions inducing protein interactions [25]. Power nodes are sets of nodes and power edges connect power nodes. A power edge between two power nodes signifies that all nodes of the first set are connected to all nodes of the second set. Note that nodes within a power node are not necessarily connected to each other.
